

El Niño affected two-thirds of the world's harvests

According to researchers at Aalto University, Finland, large-scale weather cycles, such as the one related to the El Niño phenomenon, affect two-thirds of the world's cropland. In these so-called climate oscillations, air pressure, sea level temperature or other similar factors fluctuate regularly in areas far apart in a way that causes rain and temperature patterns to shift significantly.

“During recent years, researchers’ ability to predict these oscillations has improved significantly. With this research, we highlight the potential of utilising this improved forecasting skill in agricultural planning. This could improve the resilience of agriculture to climate-related shocks, which can improve food security in many areas across the globe”, says Matias Hein, a doctoral candidate at Aalto University.

The study, published in *Nature Communications* is the first global study which examines the impacts of the El Niño-Southern Oscillation as well as the similar North Atlantic Oscillation (NAO), and the Indian Ocean Dipole, on global food crop production.

Impact on crop productivity

These climate oscillations can be divided into different episodes depending on their phase. It is already known that El Niño and its opposite phase, La Niña have a clear effect on corn, soy, rice, and wheat yields in many areas across South Asia, Latin America and southern Africa.

“Our study showed that the North Atlantic Oscillation significantly affects crop production in many parts of Europe, but also North Africa and the Middle East,” says assistant professor Matti Kummu from Aalto University.

The NAO describes the relationship between the Icelandic low pressure and the Azores high-pressure areas. When the air pressure in Iceland is significantly lower than in the Azores, stronger winds increase the transport of warm, moist air from the Atlantic to Europe. During the other phase of the NAO, when the air pressure difference is smaller, less than average amounts of mild air flow to Europe. It makes the winters colder and less rainy.

When the Atlantic air pressure difference has been high, the productivity of crops in Europe has reduced by 2% compared to the average. The effect has been particularly strong in places like Spain and the Balkans, where the decrease in productivity has been as much as 10%. Crop productivity reductions, by up to 6%, were also observed in North Africa and the Middle East. During the other phase of NAO, when the air pressure difference is weaker, the same areas have shown

positive changes in crop productivity.

In the Indian Ocean Dipole (IOD), the surface water temperature of the Indian Ocean fluctuates regularly in the ocean's eastern and western parts. When the surface water is warmer in the Western Indian Ocean, the temperatures in the Eastern Indian Ocean tend to be lower, and vice versa. The IOD phenomenon affects food crop production particularly in Australia where the crop productivity may, depending on IOD's phase, be up to 8% smaller or 6% larger compared to the average.

This study has been conducted in collaboration with researchers from Columbia University, Vrije Universiteit Amsterdam, Potsdam Institute for Climate Impact Research (PIK), and the University of Bonn.
